**ARTICLE INFO**

Keywords: DKMQ24
Composite shell element
Naghdi-Reissner-Mindlin shell theory

**ABSTRACT**

In this work we propose a new 4-node DKMQ24 shell element based on Naghdi-Reissner-Mindlin shell theory with 24 degrees of freedom. This new composite shell element, which is developed from DQM plate and shell elements, takes into account shear deformation, coupled bending-membrane energy and warping effects. This element has no spurious mode, passes patch tests for membrane, bending and shear problems. It has also successfully passed standard benchmark tests in the case of thick and thin shells without membrane and shear locking. In this paper, we extend the predictive capabilities of the DKMQ24 shell elements to composite laminated plates and shell structures. Numerical results obtained from DKMQ24 are compared against state-of-the-art shell elements. The results obtained by the proposed element converge more rapidly towards the reference solution.

1. Introduction

An ideal shell element for composite structures should be capable of modelling arbitrary shape of curved shell geometries and taking into account membrane, bending, couple membrane-bending and shear effects. The element formulation should be simple, avoiding whenever possible displacement derivatives as nodal variables, which require higher order continuity. Finally, it should be able to satisfy the rigid body and constant strain patch tests, be free of membrane and shear locking, as well as of spurious internal modes, be easily combined with other element types and able to provide accurate results for a coarse mesh.

The two main theories in shell analysis that are at our disposal for the theoretical formulation are the Kirchhoff-Love [1] and Naghdi-Reissner-Mindlin [2–7]. The first theory is only valid for thin shells and requires \( C^0 \) continuity, which is not easy to achieve for standard finite elements. For development of shell elements, it is thus easier to use the second theory, which requires only \( C^1 \) continuity. This theory, also known as shear deformable theory, is by far more popular for structural FEA (Finite Element Analysis).

The main challenge for low order Lagrange shell elements, based on Naghdi-Reissner-Mindlin hypothesis, concerns severe membrane and shear locking [8–11]. Locking cure has been an active domain of research where several different methods have emerged. The simplest cure of reduced and selective integration techniques [12–22] can successfully reduce the numerical locking. The excessive bending stiffness of the fully integrated shell element is reduced, lowering the number of Gauss points in the numerical integration of the membrane and transverse shear terms. However, reduced and selective integration can induce additional zero eigenvalues in the element stiffness matrix due to spurious modes in addition to the rigid body modes.

A more efficient cure is ANS (Assumed Natural Strains) [23–26] methods that exhibit better accuracy and robustness. The MITC4 (Mixed Interpolation of Tensorial Components) method has been effectively adopted for alleviating shear and membrane locking present in shell finite elements. The 4-node shell element MITC4 has been widely used in engineering practice due to its simple formulation and excellent performance [27]. A 3-node MITC3 shell element also is proposed [28], and this development is still being improved [29,30] with 3-nodes MITC3+ and MITC4+ elements. The DSG (Discrete Shear Gap) method developed by Bletzinger et al. to reduce shear locking [31] and the 3-node and 4-node DSG shell elements were also proposed. When used for plates, the 4-nodes DSG shell element formulation gives the MITC4 [27] element.

The development of 3-node DKT [32] and 4-node DKQ [33] elements for thick plate using ANS and Discrete Shear method to take into account the shear strains was proposed by Batoz and Lardeur [10,34,35]. These two elements rely on Reissner-Mindlin plate equilibrium equations to account for shear effects. The first one, called DST (Discrete Shear Triangular) [34], has 9 d.o.f and the second one, called DSQ (Discrete Shear Quadrilateral) [35] has 12 d.o.f. The numerical results of DST and DSQ elements converge towards those of DKT and DKQ plate elements for thin plate problems. Unfortunately, these two elements do not pass the patch test when applied to thick plate problem. To improve DST element, DST-BK has been proposed by Batoz and Katili [36] using free formulation method and incompatible modes.

The element passes the patch tests when applied to thin and thick problems, and gives good and comparable results to DKT and DST.

A 4-nodes quadrilateral plate element called PQI with a set of incompatible modes is presented in [37–39]. In an analysis of thin plates, the element exhibits a similar performance as the well-known DKQ element. However, as opposed to the DKQ element, the element PQI can also be used successfully in an analysis of thick plates. Katili [40,41] also introduced DKMT and DKMQ elements to analyze thick and thin plate problems. These elements are based on Reissner-Mindlin [6,7] hypothesis, which requires only C0 continuity. In the case of thin plate problems, the solutions obtained from DKMT element converge to DKT [32] element, while the solutions obtained from DKMQ element converge to DKQ [33] element. The problem of shear locking, when the thickness of the plate decreases, is resolved using the Discrete Kirchhoff Mindlin method, as proposed by Katili [40,41]. Therefore, DKMT and DKMQ elements are free of shear locking and passed the associated classical patch tests. The application of DKMQ plate element in stochastic finite element analysis, error estimation and buckling analysis were presented in [42–44]. The performance of DKMQ and DKMT plate element has been proved for thin and thick plate problems including composite plates [45,46]. Others papers in finite element for composite plates are found in [47–51]. Following the robustness of DKMQ plate element, 4-nodes DKMQ shell elements with 24 dof and 20 dof have been proposed [52–54].

A new development based on a modified Timoshenko beam theory and modified Reissner-Mindlin plate theory approach has been proposed recently for beam [55,56] and plate bending problems in isogeometric and finite element analysis [57–59]. Using unified and integrated (UI) approach [56,59], the total displacement is split into bending displacement and shear displacement which causes the rotations, curvatures and shear deformations can be defined as first, second and third derivatives of bending displacement, respectively. The shear-locking problem does not occur due to the strong interdependence among the bending displacement and rotations.

The main objective of this work is to build on our previous work [52] to study composite shell structures. The DKMQ24 shell element take into account coupled bending-membrane energy and warping effects. The DKMQ24 element passes the classical patch tests in thick and thin plate configurations, and the solutions converge quickly towards the reference values without shear locking. In this paper, we present a new development with DKMQ24 shell element for composite structures.

The paper is organized as follows. The geometry of shell element explained in Section 2. The constitutive laws at the level of a single laminate and at the stress resultant level are presented in Section 3 and 4, respectively. The shell kinematics for displacements and rotations are explained in Section 5. Furthermore, Section 6 presents the formulation of membrane deformation and curvatures strain, and Section 7 presents the assumed shear strain field. The element stiffness matrix including fictitious stiffness is explained in Sections 8 and 9. The numerical test results for composite plates and shells are shown in Section 10. In Section 11, we state the conclusions.

2. Geometric description of the DKMQ24 shell element

The geometry of the shell is defined with respect to a global Cartesian coordinate system X, Y, Z (Fig. 1) with associated unit vectors Xi, Yi, Zi (Fig. 2). This system defines the directions for the global displacements Ui, Vi, W associated with the axes X, Y, Z, respectively. A nodal Cartesian coordinate system formed by unit vectors Xq, Yq, Zq is defined at each node i on the reference surface (Fig. 2), see [11] for further detail.

The geometry of the shell is discretized by a mesh of quadrilateral elements with 4-nodes, which are not necessary in the same plane [52]. The position vector xi in the middle surface is continuous, but the direction of normal vector ni may be discontinuous between two adjacent elements. The vector ni can be defined as the average of all the normal vectors at node i, corresponding to the elements attached to node i. This ensures geometric compatibility for coarse meshes and folded shells.

The interpolation of a position vector xi at an arbitrary point q is expressed as a function of the parametric coordinate ξ, η, z with z the thickness coordinate:

\[ x_i(ξ, η, z) = x_i(ξ, η) + z g(ξ, η) \]  

(1)

\[ x_i(ξ, η, z) = \sum_{i=1}^{4} N_i(ξ, η) x_i + z \sum_{i=1}^{4} N_i(ξ, η) n_i \]  

(2)

where:

- \( x_i \) is the position vector of an arbitrary point p in the middle surface with \( z = 0 \) in the global Cartesian coordinate system (X, Y, Z), which is defined in \( (ξ, η, z = 0) \).
- \( x_i \) is the position vector of an arbitrary point q \( (X_q, Y_q, Z_q) \) in the global Cartesian coordinate system, which is defined in \( (ξ, η, z = 0) \).
- \( x_i \) is the coordinate of an arbitrary nodal i \( (X_i, Y_i, Z_i) \) in the global Cartesian coordinate system \( (ξ, η) \) is the shape function of the quadrilateral element depending on the parametric coordinates \( (ξ, η) \) in the reference element (Table 1). \( n_i \) denotes the normal direction at the surface of the shell element node i (Fig. 1).
\[ \frac{1}{2}(1 - \xi^2)(1 - \eta^2) \]

and

\[ \frac{1}{2}(1 + \xi)(1 - \eta^2) \]

\[ \frac{1}{2}(1 - \xi)(1 + \eta) \]

\[ \frac{1}{2}(1 - \xi)(1 - \eta) \]

\[ \frac{1}{2}(1 + \xi)(1 + \eta) \]

\[ \frac{1}{2}(1 - \xi^2)(1 - \eta^2) \]

\[ \frac{1}{2}(1 + \xi^2)(1 - \eta^2) \]

\[ \frac{1}{2}(1 - \xi)(1 + \eta^2) \]

\[ \frac{1}{2}(1 + \xi)(1 + \eta^2) \]

- Local basis at \( z = 0 \):

We define the covariant coordinate system by using the isoparametric coordinates for shell analysis. The relationship between differential elements in Cartesian and natural coordinates at point \( p \) can be written as

\[
d\mathbf{x}_p = \begin{bmatrix} dX \\ dY \\ dZ \end{bmatrix} = [\mathbf{B}_1 \ \mathbf{B}_2] \begin{bmatrix} dx \\ dy \\ dz \end{bmatrix}
\]

Vectors \( \mathbf{g}_1 \) and \( \mathbf{g}_2 \) are tangential vectors in direction \( \xi \) and \( \eta \). In general \( \mathbf{g}_i \) and \( \mathbf{g}_j \) are not orthogonal, and they are used to construct the covariant basis. Vectors \( \mathbf{g}_1 \) and \( \mathbf{g}_2 \) (Fig. 2) are given by

\[
\mathbf{g}_i = \mathbf{x}_{p,\xi} = \sum_{i=1}^{4} N_i \xi \xi ; \quad \mathbf{g}_2 = \mathbf{x}_{p,\eta} = \sum_{i=1}^{4} N_i \eta \eta
\]

where \( N_i \xi \) and \( N_i \eta \) are the first derivatives of the shape functions \( N_i \) with respect to \( \xi \) and \( \eta \). The convention in this paper for \( f_\xi \) will denote the partial derivative of function \( f \) with respect to \( \xi \).

The local basis at \( z = 0 \), \( [F_0] \), is written as:

\[
[F_0] = [g_0 \ g_2]
\]

\[
det[F_0] = (g_1 \times g_2) \cdot \mathbf{n} = \frac{a_{12} \ a_{22} - a_{12} \ a_{22}}{1 + \mathbf{n} \cdot \mathbf{n}}
\]

The length \( ds \) on the surface is classically given by:

\[
(ds)^2 = \mathbf{g} \cdot \mathbf{g} = \left( \frac{dx}{dz} \right)^2 + \left( \frac{dy}{dz} \right)^2 + \left( \frac{dz}{dz} \right)^2
\]

We denote by \( [a] \) the metric tensor in the middle surface. It is a symmetric \((a_{ij} = a_{ji})\), positive-definite matrix defined as:

\[
[a] = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix} = \begin{bmatrix} \mathbf{g}_1 \cdot \mathbf{g}_1 & \mathbf{g}_1 \cdot \mathbf{g}_2 \\ \mathbf{g}_2 \cdot \mathbf{g}_1 & \mathbf{g}_2 \cdot \mathbf{g}_2 \end{bmatrix}
\]

\[ \det[a] = a_{11} > 0 ; \quad a_{22} > 0 ; \quad \det[a] > 0
\]

The area of an element \( d\mathbf{A} \) expressed as:

\[
d\mathbf{A} = g_1 \mathbf{dx} \mathbf{d} \eta \mathbf{n} = |\mathbf{g}_1 | \mathbf{g}_2 \mathbf{d} \xi \mathbf{d} \eta \mathbf{n}
\]

\[ d\mathbf{A} = \sqrt{a} \mathbf{d} \xi \mathbf{d} \eta \mathbf{n} = d\mathbf{A} \mathbf{n} ; \quad d\mathbf{A} = \sqrt{a} \mathbf{d} \xi \mathbf{d} \eta \mathbf{n}
\]

To simplify the calculations, we introduce the vectors \( \mathbf{g}^1 \) and \( \mathbf{g}^2 \) which are the classical contravariant vectors (Fig. 3). We recall that contravariant vectors satisfy:

\[
\mathbf{g}^1 \cdot \mathbf{g}_1 = \mathbf{g}^2 \cdot \mathbf{g}_2 = 1 ; \quad \mathbf{g}^1 \cdot \mathbf{g}^2 = \mathbf{g}^2 \cdot \mathbf{g}^1 = 0
\]

The inverse matrix \([F_0]^{-1} \), with \([F_0]^{-1}[F_0] = [I] \), can be written as:

\[
[F_0]^{-1} = [\mathbf{g}^1 \ \mathbf{g}^2] [a]^{-1}
\]

The contravariant base vectors \( \mathbf{g}^1 \) and \( \mathbf{g}^2 \) are given by:

\[
\mathbf{g}^1 = \frac{1}{a} (a_{12} \mathbf{g}_1 - a_{12} \mathbf{g}_2) ; \quad \mathbf{g}^2 = \frac{1}{a} (-a_{22} \mathbf{g}_1 + a_{12} \mathbf{g}_2)
\]

The relationship (3) can also be written in compact notation:

\[
\begin{bmatrix} d\xi \\ d\eta \end{bmatrix} = \begin{bmatrix} \mathbf{g}^1 \\ \mathbf{g}^2 \end{bmatrix} \begin{bmatrix} dX \\ dY \\ dZ \end{bmatrix}
\]

The covariant and contravariant systems are important for developing consistent expressions for the shell curvatures and the equilibrium equations in shell theory. The relation of differential calculation between global coordinate system \( X, Y, Z \) and local coordinates system \( x, y, z \) can be written (Fig. 4) as:

\[
\begin{bmatrix} dX \\ dY \\ dZ \end{bmatrix} = [Q] \begin{bmatrix} dx \\ dy \\ dz \end{bmatrix}
\]

where:

\[
[Q] = \begin{bmatrix} L_1 & L_2 & L_3 \\ L_4 & L_5 & L_6 \end{bmatrix}
\]

\[
L_1 = n \times k ; \quad L_2 = n \times \xi ; \quad L_3 = \xi \quad \text{if} \quad n = \pm k
\]

Relationships (12) and (13) become

\[
\begin{bmatrix} d\xi \\ d\eta \end{bmatrix} = [C] \begin{bmatrix} dx \\ dy \end{bmatrix}
\]

\[
[C] = \begin{bmatrix} C_{11} & C_{12} \\ C_{21} & C_{22} \end{bmatrix} = \begin{bmatrix} g^1 \cdot L_1 & g^2 \cdot L_1 \\ g^1 \cdot L_2 & g^2 \cdot L_2 \end{bmatrix}
\]

- Local Basis at \( z = 0 \):

The local basis \([F_0] \) at \( z = 0 \) at an arbitrary point \( q \) outside of shell
mid-surface can be written as:

\[ F_i = [g_{iz}, g_{iz}] = [F_i] + z[F_e] \]

where

\[ F_i = [F_{ij} [0_0_0]] : [F_i] = [F_i]([I] + [z(b_n)]) \]

With \([I]\) as the identity matrix, and

\[ \begin{bmatrix} \bar{b}_{n1} & \bar{b}_{n2} & 0 \\ \bar{b}_{n2} & \bar{b}_{n1} & 0 \\ 0 & 0 & 0 \end{bmatrix}, \]

\[ \begin{bmatrix} \bar{g}_{11} & \bar{g}_{12} & 0 \\ \bar{g}_{12} & \bar{g}_{22} & 0 \\ 0 & 0 & 0 \end{bmatrix} \]

If the four nodes in an element are coplanar, then the matrix \([b_n]\) has a zero column because \(n\) is constant in this element.

3. Constitutive laws

In local Cartesian coordinate systems \((x, y, z)\), we can write the constitutive laws for in-plane stresses in each laminate as:

\[ \sigma = [H]\epsilon \]

where in-plane stresses are:

\[ \sigma = \langle x, y, \sigma_0 \rangle \]

and membrane strain and curvatures are

\[ \epsilon = [e, \chi] \]

\[ \epsilon = \langle e, \chi, \epsilon_0 \rangle \]

The relation between out-of-plane shear stress and shear strain can be written as:

\[ \tau = [G] \gamma; \tau = \langle \tau_x, \tau_y \rangle \]

The last result can be simplified for the isotropic material

\[ [H] = \frac{E}{1 - \nu} \begin{bmatrix} 1 & \nu & 0 \\ \nu & 1 & 0 \\ 0 & 0 & (1-\nu)/2 \end{bmatrix} \]

where \(E\) is the Young modulus of elasticity, \(G\) is the shear modulus, \(\nu\) the Poisson ratio.

4. Stress resultants

The stresses resultants are integral of the local Cartesian stress component \(\sigma_x, \sigma_y, \sigma_{0y}, \tau_x\) and \(\tau_y\) given by:

\[ N_x = \int_{h/2}^{h/2} \sigma_x dz; \quad N_y = \int_{h/2}^{h/2} \sigma_y dz \\
N_{0y} = \int_{h/2}^{h/2} \sigma_{0y} dz \\
M_x = \int_{h/2}^{h/2} \sigma_x z dz; \quad M_y = \int_{h/2}^{h/2} \sigma_y z dz \\
M_{0y} = \int_{h/2}^{h/2} \sigma_{0y} z dz \\
T_x = \int_{h/2}^{h/2} \tau_x dz; \quad T_y = \int_{h/2}^{h/2} \tau_y dz \]

The five independent coefficients can be either

\[ H_{LL}, H_{LT}, H_{TT}, G_{LT} = G_{TZ} \quad \text{or} \quad E_i, E_T, \sigma_i \left( \text{or} \sigma_T \right) \text{with} \quad \sigma_i = \frac{E_i}{1 + \nu} \]

\[ G_{LT} = G_{TZ} \quad \text{or} \quad \sigma_T \quad \text{with} \quad G_T = \frac{E_T}{1 + 2\nu} \]

where \(E_i\) is the Young modulus in the fibre direction and \(E_T\) is the Young modulus in the transverse direction to the fibre, \(\sigma_T\) and \(\sigma_i\) are the Poisson ratios in the \(L-T\) plane of orthotropic layer. The constitutive parameters in matrices \([H_i]\) and \([G_i]\) can be measured experimentally. The orthotropic directions \(L\) and \(T\) can vary from layer to layer, and are represented by angle \(\theta\) between the local axis \(x\) and the directions \(L_i\) of the \(i\)th layer (Fig. 5). The matrix transformation from orthotropic to local Cartesian coordinates can be written as

\[ [R_{L1}] = \begin{bmatrix} C_0^2 & S_0^2 & C_0 S_0 \\ S_0^2 & C_0^2 & -C_0 S_0 \\ -2C_0 S_0 & 2C_0 S_0 & C_0^2 - S_0^2 \end{bmatrix} \]

and: \([R_{L2}] = \begin{bmatrix} C_0 & S_0 & 0 \\ -S_0 & C_0 & 0 \\ 0 & 0 & 1 \end{bmatrix}\]

where: \([H_i] = [R_{L1}]^T[L_i][R_{L1}] \]

\[ [G] = [R_{L2}]^T[G_i][R_{L2}] \]

Fig. 5. Orthotropic layer.
composite shell, which are denoted as \([H_m], [H_b], [H_{nb}]\) and \([H_i]\) matrices (see Fig. 6).

Membrane constitutive matrix:

\[
[H_m] = \begin{bmatrix}
H_{m11} & H_{m12} & H_{m13} \\
\text{Sym.} & H_{m22} & H_{m23} \\
H_{m31} & H_{m32} & H_{m33}
\end{bmatrix} = \sum_{i=1}^{nl} [H_i] h_i
\]  

(34)

where \(h_i = (z_{i+1} - z_i)\)

Bending constitutive matrix:

\[
[H_b] = \begin{bmatrix}
H_{b11} & H_{b12} & H_{b13} \\
\text{Sym.} & H_{b22} & H_{b23} \\
H_{b31} & H_{b32} & H_{b33}
\end{bmatrix} = \frac{1}{2} \sum_{i=1}^{nl} [H_i] (z_{i+1} - z_i)^2
\]  

(35)

Coupled membrane-bending constitutive matrix:

\[
[H_{nb}] = \begin{bmatrix}
H_{nb11} & H_{nb12} & H_{nb13} \\
\text{Sym.} & H_{nb22} & H_{nb23} \\
H_{nb31} & H_{nb32} & H_{nb33}
\end{bmatrix} = \frac{1}{2} \sum_{i=1}^{nl} [H_i] h_i \tilde{z}_i
\]  

(36)

where \(h_i\) is the layer thickness.

If the material properties and the laminate orientations are symmetric with respect to the middle surface, \([H_{nb}]\) is zero and the middle surface \(xy\) is a neutral surface. Middle surface \(xy\) then coincides with the neutral surface and the membrane and bending effects are uncoupled. This means that in-plane forces acting on neutral surface do not produce any curvatures and, conversely, bending moments do not produce any membrane strain.

Shear constitutive matrix:

\[
[H_s] = \begin{bmatrix}
\Pi_{s11} & \Pi_{s12} \\
\text{Sym.} & \Pi_{s22}
\end{bmatrix} = \sum_{i=1}^{nl} [G_i] h_i
\]  

(37)

where \(nl\) is the number of layers in the structures. \([H_i]\) is the in-plane constitutive matrix for \(i\)th layer and \([G_i]\) is the out-of-plane constitutive matrix for \(i\)th layer. They are defined in (28) for orthotropic material and in (29) for isotropic material. Matrix \([H_i]\) is defined so that the shear strain energy density obtained for an exact 3D distribution of the transverse shear stresses \(\tau_x\) and \(\tau_y\) is identical to the shear energy associated with the Naghdi-Reissner-Mindlin plate model. The requirement that the transverse shear stiffness of the shell model should correspond as much as possible with respect to the one from 3D analysis is met by using the modified constitutive matrix \([H_i]\) for the shear forces (37) which can be written as

\[
[H_i] = \begin{bmatrix}
\kappa_{i11} & \Pi_{i11} \\
\text{Sym.} & \kappa_{i22} & \Pi_{i22}
\end{bmatrix}
\]  

(38)

where \(\kappa_{i11}, \kappa_{i22}\) are the transverse shear correction parameters.

For isotropic material, we can simplify these constitutive matrices.

The matrix \([H_m], [H_b]\) and \([H_i]\) are then given by:

\[
[H_m] = \begin{bmatrix}
D_m & 0 & 0 \\
0 & D_m & 0 \\
0 & 0 & 0
\end{bmatrix} = \frac{Eh}{1-\nu^2}
\]  

(39)

\[
[H_b] = \begin{bmatrix}
D_b & 0 & 0 \\
0 & D_b & 0 \\
0 & 0 & D_b
\end{bmatrix} = \frac{Eh^3}{12(1-\nu^2)}
\]  

(40)

\[
[H_{nb}] = [0]
\]  

(41)

\[
[H_i] = D_i \begin{bmatrix}
1 & 0 & 0 \\
0 & 1 & 0 \\
0 & 0 & 1
\end{bmatrix} = xGh
\]  

(42)

For the isotropic material we typically chose \(\kappa = 5/6\), which is computed as the transverse shear correction parameters of (38) based on considerations of static equivalences [10].

5. Kinematics of D KMQ24 shell element

There are 24 degrees of freedom on each element, three displacements and three rotations at each node \((u, v, w, \theta_x, \theta_y, \theta_z)\) in the global coordinate system (Fig. 7).

For the approximation of displacement in the middle surface, \(\bar{u}_p(\xi,\eta)\), the element uses a linear function. For the interpolation of rotations \(\hat{\beta}(\xi,\eta)\), D KMQ24 uses an incomplete quadratic polynomial. The displacement of point outside mid-surface \(u_{Nq}\) can then be written as [52]

\[
u_{Nq}(\xi,\eta,z) = \bar{u}_p(\xi,\eta) + z \hat{\beta}(\xi,\eta)\]

with: \(\hat{\beta} \cdot \hat{r} = 0\)

(43)

where mid-surface displacement is bi-linear:

\[
u_p(\xi,\eta) = \sum_{i=1}^{4} N_i(\xi,\eta) \begin{bmatrix} U_i \\ V_i \\ W_i \end{bmatrix}
\]

(44)

The rotation approximation for \(\hat{\beta}\) is incomplete bi-quadratic function.

\[
\hat{\beta}(\xi,\eta) = \sum_{i=1}^{4} N_i(\xi,\eta) \begin{bmatrix} \Delta \theta_{x,i} \\ \Delta \theta_{y,i} \end{bmatrix} + \sum_{i=1}^{4} P_{k,i}(\xi,\eta) \bar{t}_{ki} \Delta \beta_{ki}
\]

(45)
\[ \ddot{\theta} = \sum_{i=1}^{n} N_i[RN_i] \begin{bmatrix} \dot{\theta}_i \\ \ddot{\theta}_i \end{bmatrix} + \sum_{k=5}^{n} P_k L_{ak} \Delta \beta_{ak} \]  
(46)

\[
[RN] = [[RN1]; [RN2]; [RN3]] = \begin{bmatrix} 0 & n_{i1} & -n_{i2} \\ -n_{i1} & 0 & n_{i3} \\ n_{i2} & -n_{i3} & 0 \end{bmatrix}
\]  
(47)

where \(N_i\) is a linear function and \(P_k\) is a quadratic function (see Table 1); \(\Delta \beta_{ak}\) \((k = 5, 6, 7, 8)\) is a supplementary degree of freedom on each side of the element, which represents a hierarchical rotation with respect to the average of \(\beta_{ai}\) and \(\beta_{aj}\) in the middle of each side (Fig. 8), \(L_{ak}\) is the length of side \(i j\).

The rotation components \(\beta_i\) and \(\beta_m\) are defined according:
\[
\beta_i = \ddot{\beta}_i L_{ak} \quad \beta_m = \ddot{\beta}_m L_{mk} \quad L_{mk} = L_{ak} \wedge b_k
\]  
(48)

where \(L_{ak}\) and \(L_{mk}\) \((k = 5, 6, 7, 8)\) are the unit vector tangential and normal to the side of \(k\) (Fig. 9). We note the rotation \(\beta_{im}\) (in the plane \(z-m\), where \(s\) is the tangential coordinate on the considered side of \(i j\)) as a quadratic function with respect to \(s\). The rotation component \(\beta_{im}\) (in the plane \(z-m\) where \(m\) is perpendicular to \(s\) and \(g\) ) as a linear function in \(s\) (Fig. 8). For example, along the side of \(i j\), we have
\[
\beta_i = \left(1 - \frac{s}{L_{ak}} \right) \frac{\Delta \beta_{ak}}{2} + \frac{s}{L_{ak}} \frac{\Delta \beta_{ak}}{2}
\]
\[
\beta_m = \left(1 - \frac{s}{L_{ak}} \right) \frac{\Delta \beta_{ak}}{2} + \frac{s}{L_{ak}} \frac{\Delta \beta_{ak}}{2}
\]  
(49)

6. Approximation of membrane strains and curvatures

We take from [52] the approximation for membrane strains which can be written as
\[
[e] = \begin{bmatrix} e_1 \\ e_2 \end{bmatrix} = \begin{bmatrix} L_1 & 0 \\ 0 & L_2 \end{bmatrix} \begin{bmatrix} \beta \gamma \end{bmatrix}
\]  
(50)

By introducing (44) into (50), we get:
\[
[e] = [B_{ak}][u_{ak}]
\]  
(51)

\[
[u_{ak}] = \begin{bmatrix} u_{ak1} \\ \ldots \\ u_{ak4} \end{bmatrix}
\]  
(52)

and
\[
[B_{ak}] = \begin{bmatrix} \langle t_i \rangle N_{ax} & 0 & 0 & 0 \\ \langle t_i \rangle N_{ay} & 0 & 0 & 0 \\ \langle t_i \rangle N_{ay} & \langle t_i \rangle N_{ax} & 0 & 0 \end{bmatrix}
\]  
(53)

\[N_{ax} = N_{ax} C^a_{11} + N_{ax} C^a_{21}
\]
\[N_{ay} = N_{ay} C^a_{12} + N_{ay} C^a_{22} \]  
(54)

The approximation for components of the curvature tensor is given by:

\[\Delta \beta_{sk} = \sum_{i=1}^{n} \frac{N_i[RN_i]}{2} \begin{bmatrix} \dot{\theta}_i \\ \ddot{\theta}_i \end{bmatrix} + \sum_{k=5}^{n} P_k L_{ak} \Delta \beta_{sk} \]  
(59)

\[\Delta \beta_{m} = \frac{\Delta \beta_{m}}{2} \]  
(60)

\[\Delta \beta_{sk} = \Delta \beta_{sk} \]  
(61)

\[P_{ax} = P_{axx} C^a_{11} + P_{axx} C^a_{21} ; P_{axy} = P_{axxy} C^a_{12} + P_{axxy} C^a_{22} \]  
(62)

From [52] we have:
\[[bc] = \begin{bmatrix} b_{c1} \\ b_{c2} \end{bmatrix} = [\hat{\beta}][C^a]\]  
(63)

We can see that there is a coupling between bending and membrane for the curvature strains equations in (58). This happens if the four nodes in the element are not coplanar \(|bc| \neq 0\). If the four nodes in an element are coplanar, then the matrix \(|bc| = 0\) (because \(n\) is constant for this element). In this situation the formulation will give the same results as with the flat shell model.

7. Assumed shear strain fields for DKMQ24

The key point of formulation for shear locking free in the case of composite shell structures is the choice of the assumed shear strain field. We briefly present the assumed strain fields used in the DKMQ24 shell element. The main reason for that concerns the importance of shear deformation with respect to the risk of shear failure in
composites. Shear strain field is approximately independent of displacement and rotations in the spirit of assumed shear strain. Due to the element curvature, it is convenient to express the assumed shear strain field in the covariant components \( \gamma_i \), \( \gamma_j \), and \( \gamma_k \) and then transform the resulting expressions to the local coordinate system.

The definition of the assumed shear strain field \( \gamma \) follows similar arguments to that for our plate and shell elements \([41,52]\). Namely given construction in the covariant system, we obtain the corresponding approximation in the local Cartesian system.

\[
\begin{align*}
\mathbf{\gamma} &= \begin{bmatrix} \gamma_1 \\ \gamma_2 \\ \gamma_3 \end{bmatrix} = [C]^T \begin{bmatrix} \gamma_1 \\ \gamma_2 \\ \gamma_3 \end{bmatrix} = \begin{bmatrix} C_{11} & C_{12} & C_{13} \\ C_{21} & C_{22} & C_{23} \\ C_{31} & C_{32} & C_{33} \end{bmatrix} \begin{bmatrix} \gamma_1 \\ \gamma_2 \\ \gamma_3 \end{bmatrix}
\end{align*}
\]

(64)

Following the choice in \([41,52]\), we take covariant shear component approximation

\[
\begin{bmatrix} \gamma_1 \\ \gamma_2 \\ \gamma_3 \end{bmatrix} = [N_1][\mathbf{\gamma}_0]
\]

(65)

where \( \mathbf{\gamma}_0 \) denote the natural shear strains at the midpoint of the element sides 5, 6, 7, 8. On the other hand, we can replace these covariant components with the corresponding physical components simply by using the correct metric for each element side

\[
\begin{bmatrix} \gamma_1 \\ \gamma_2 \\ \gamma_3 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & L_k & 0 \\ 0 & 0 & -L_k \end{bmatrix} \begin{bmatrix} \gamma_0 \\ \gamma_0 \\ \gamma_0 \end{bmatrix} = [A_1][\mathbf{\gamma}_0]
\]

(66)

With the results (64)–(66) on hand, we obtain:

\[
\begin{align*}
\mathbf{\gamma} &= \begin{bmatrix} \gamma_1 \\ \gamma_2 \\ \gamma_3 \end{bmatrix} = [B_1][\mathbf{\gamma}_0] \\
[\mathbf{R}_1] &= [C]^T[N_1][A_1]
\end{align*}
\]

(67)

Thus the assumed independent shear strain \( \gamma \) on side-k \((k = 5, 6, 7, 8)\) (Fig. 10), can be expressed as:

\[
\gamma_k = -\frac{2}{3}\phi_0 \Delta \beta_k
\]

(68)

where the coefficient \( \phi_0 \) can be obtained for either orthotropic material \([45]\)

\[
\phi_0 = (H_{i61}^{int}H_{6j1} + H_{i72}^{int}H_{7k2} + 12/L_k^2)
\]

(69)

where \( L_k \) is the length of the side \( k \), and

\[
[H_{i61}] = [R_6]^T[H_i][R_6] \\
[H_{i72}] = [R_7]^T[H_i][R_7] \\
[H_{i61}^{int}] = [H_{i61}]^{-1}
\]

(70)

where \([R_6]\) and \([R_7]\) are given by:

\[
[R_6] = \begin{bmatrix} S_k^2 & C_k & S_k C_k \\ C_k^2 & S_k & -S_k C_k \\ -2S_k C_k & 2S_k C_k & S_k^2 -C_k^2 \end{bmatrix}
\]

(71)

or for an isotropic material \([41]\)

\[
\phi_0 = \frac{D_k}{D_i} \frac{12}{L_k^2} = \frac{2}{3(1-\nu)} \frac{H_k}{L_k^2}
\]

(72)

The factor \( \phi_0 \), characterizing the influence of shear, maintains the consistency of the proposed element. The factor \( \phi_0 \) in the above equation precisely explains why DKMQ24 element behaves as either Reissner-Mindlin theory for thick shell or as Kirchhoff-Love theory for thin shell. In the thin shell problems, where factor \( \phi_0 \) is close to zero, shear deformation is automatically reduced. Accordingly, as the main positive result, the shear locking is automatically resolved by this Discrete Kirchhoff Mindlin method. Applying the same procedure systematically on all sides of the proposed shell element, from Eq. (68) we get \([41,52]\)

\[
\begin{bmatrix} \gamma_4 \\ \gamma_5 \\ \gamma_6 \end{bmatrix} = \begin{bmatrix} \phi & 0 & 0 \\ 0 & \phi & 0 \\ 0 & 0 & \phi \end{bmatrix} \begin{bmatrix} \Delta \beta_4 \\ \Delta \beta_5 \\ \Delta \beta_6 \end{bmatrix}
\]

(73)

Finally, combining (67) and (73) we obtain:

\[
[\mathbf{\gamma}] = \begin{bmatrix} \gamma_4 \\ \gamma_5 \\ \gamma_6 \end{bmatrix} = [B_1][A_1][\Delta \beta_4]
\]

(74)

8. Variational principal and shell element stiffness matrix

The modified Hu-Washizu functional is used as the appropriate framework to develop our DKMQ24 shell element. We only briefly recall the modified Hu-Washizu principle, whose details can be found in Refs. \([60,61]\). The Hu-Washizu principle for shell can be written as:

\[
\Pi = \Pi_{int} - \Pi_{ext}
\]

(75)

\[
\Pi_{int} = \Pi_{int}^w + \Pi_{int}^{mb} + \Pi_{int}^{mb}
\]

(76)

\[
\Pi_{ext} = \int_A w f_z dA
\]

(77)

where \( f_z \) is the distributed load in the \( z \) direction, \( \Pi_{int}^w, \Pi_{int}^{mb}, \Pi_{int}^{mb} \) and \( \Pi_{ext} \) are respectively, membrane, bending, coupled membrane-bending and shear strain energy. The latter is the main reason why we need the Hu-Washizu formulation to define the assumed shear strain which reads

\[
\Pi_{int}^{mb} = \frac{1}{2} \int_A <\mathbf{\gamma}^2[H_{i61}]^{int}dA + \int_A <T>T^T[\mathbf{\gamma}][\mathbf{\gamma}]dA
\]

(78)

By computing the variation of \( \Pi_{int}^{mb} \) with respect to \( T \) (shear force), we get the following orthogonality condition:

\[
\int_A <\mathbf{\gamma}^2(T)[\mathbf{\gamma}]-[\mathbf{\gamma}]dA = 0
\]

(79)

This equation can be viewed as a constraint equation to be imposed on each element edge:
\[ \int_0^{l_k} \delta \phi (\gamma_k - L_k) \, ds = 0 \; ; \; k = 5,6,7,8 \]  

(80)

From (80) we can defined the kinematic relationships between the assumed shear strain \( \gamma_k \), as a constant on each sides and \( L_k \) according to

\[ \gamma_k = \frac{1}{L_k} \int_0^{l_k} \gamma_k \, ds \; ; \; k = 5,6,7,8 \]  

(81)

where

\[ \gamma_k = \mu_B \cdot \beta_k + \frac{\partial}{\partial x_k} L_k \]  

(82)

By introducing (82) into (81), we have

\[ L_k = \frac{1}{L_k} \int_0^{l_k} \left( \mu_B \cdot \beta_k + \frac{\partial}{\partial x_k} L_k \right) \, ds \]  

(83)

where \( \beta_k \) is the unit exterior normal vector on the corresponding side of the element. On each side-\( k \), we obtain those normal vectors by averaging the nodal values

\[ \beta_k = \frac{1}{2} (\beta_l + \beta_r) \]  

(84)

By introducing (68) into (83), we obtain

\[ -\frac{2}{3} \phi \Delta \beta_k = \frac{1}{L_k} \int_0^{l_k} \left( \mu_B \cdot \beta_k + \frac{\partial}{\partial x_k} L_k \right) \, ds \]  

(85)

Moreover, from (44) to (49) we have

\[ \mu_B = \frac{1}{L_k} (\mu_l - \mu_r) \]

\[ \frac{\partial}{\partial x_k} L_k = \beta_k = \left( 1 - \frac{1}{L_k} \right) \beta_k + \frac{4}{L_k^2} \left( L_k - \frac{1}{L_k} \right) \Delta \beta_k \]  

(86)

Finally, from (85) and (86), we have:

\[ -\frac{2}{3} \phi (1 + \phi_k) \Delta \beta_k = \frac{1}{L_k} < n \cdot n > n_k n_k > \left( \begin{array}{c} U_j - U_i \\ V_j - V_i \end{array} \right) \]

\[ \Rightarrow \frac{1}{L_k} \left( \begin{array}{c} U_j - U_i \\ V_j - V_i \end{array} \right) \]

(87)

With transformation in (87) applied on all four sides, the independent parameter \( \Delta \beta_k \) becomes a function of degrees of freedom \( \left( u_m \right) \) namely

\[ \Delta \beta_k = [A_k]^{-1} [A_k] |u_m| \]  

(88)

where:

\[ [A_k] = -\frac{2}{3} \left( \begin{array}{cccc} 1 + \phi_k & 0 & 0 & 0 \\ 0 & 1 + \phi_k & 0 & 0 \\ 0 & 0 & 1 + \phi_k & 0 \\ 0 & 0 & 0 & 1 + \phi_k \end{array} \right) \]  

(89)

Substituting (88) into (56) we obtain the final expression of the curvature

\[ [\chi] = [B_k(\xi \eta)] |u_m| \]

\[ [B_k(\xi \eta)] = [B_k(\xi \eta)] + [B_{k\beta}(\xi \eta)] [A_k]^{-1} [A_k] \]  

(90)

Substituting (88) into the expression of transversal shear strain deformation (74), we obtain:

\[ [\gamma] = [B_k(\xi \eta)] |u_m| \]

\[ [B_k(\xi \eta)] = [B_k(\xi \eta)] [A_k] [A_k] \]  

(91)

where:

\[ [A_k] = \left[ \begin{array}{cccc} t_k & 0 & 0 & 0 \\ 0 & t_k & 0 & 0 \\ 0 & 0 & \phi_2 & 0 \\ 0 & 0 & 0 & \phi_2 \end{array} \right] \]  

(92)

When \( h \ll L_k \), it can easily be seen from the last result that \( \phi_k \) becomes very small and consequently:

- Matrix \([A_k]\) and bending energy for DKMQ24 will be equal with DKQ24 element in Ref. [62], therefore there is no shear locking for thin shell.
- Matrix \([A_k] \approx [0] \) and shear energy becomes zero, and the DKMQ24 element will converges to DKQ24 element in Ref. [62].

When \( h \gg L_k \), it can easily be seen that \( \phi_k \) becomes very large and consequently:

- Matrix \([A_k]^{-1} \approx [0] \) and \([\Delta \beta_k] \approx [0] \); therefore, the bending strain matrix \([B_k]\) from (90) for DKMQ24 element will be almost identical to the bending strain matrix of Q4V24 [11,52] element equivalent of MITC4 [27].

- Matrix \([A_k] \approx [I] \), therefore, the shear strain matrix \([B_k]\) defined in (91) for DKMQ24 element will be almost identical with the shear strain matrix for the Q4V24 [11,52] element equivalent of MITC4 [27].

- For plates, DKMQ24 gives the same results as DKMQ [41] plate bending element and converges to MITC4 plate bending element [63].

For an element with the area \( A \), the membrane strain energy (76) can be written as

\[ \Pi^m_{int} = \frac{1}{2} \int_A \epsilon [H_m] [\epsilon] \, dA = \frac{1}{2} [u_m] [k_m] [u_m] \]  

(93)

where

\[ [k_m] = \int_A [B_m]^T [H_m] [B_m] \, dA \]  

(94)

In a similar way, the bending deformation energy (76) for an element with the area \( A \) is given by

\[ \Pi^b_{int} = \frac{1}{2} \int_A [\chi] [H_b] [\chi] \, dA = \frac{1}{2} [u_m] [k_b] [u_m] \]  

(95)

leading to the bending part of the proposed shell element stiffness

\[ [k_b] = \int_A [B_b]^T [H_b] [B_b] \, dA \]  

(96)

The membrane-bending coupling effects energy (76) for an element with the area \( A \) is given by

\[ \Pi^c_{int} = \frac{1}{2} \int_A \epsilon [H_m] [\chi] \, dA + \frac{1}{2} \int_A [\chi] [H_m] [\epsilon] \, dA \]

\[ \Pi^c_{int} = \frac{1}{2} [u_m] (k_m + k_b)^T [u_m] \]  

(97)

leading to the coupling term of the shell element stiffness

\[ [k_m] = \int_A [B_m]^T [H_m] [B_m] \, dA \]

(98)

Finally, transversal shear strain energy (76) for an element with the mid-surface area \( A \) is:

\[ \Pi^t_{int} = \frac{1}{2} \int_A [\gamma] [H_t] [\gamma] \, dA = \frac{1}{2} [u_m] [k_s] [u_m] \]  

(99)

which allows us to define the shear term of the shell element stiffness matrix
\[ [k_{n}] = \int_{A} [B]^T [H_i] [B] dA \]  

(100)

In summary, the stiffness matrix \([k]\) is the assembly of the stiffness matrices due to membrane, bending, coupled membrane-bending and transversal shear.

\[ [k] = [k_m] + [k_b] + [k_{mbl}] + [k_i] \]  

(101)

The stiffness matrix is determined using the Gauss numerical integration. The standard Gauss integration rule with 2 × 2 points is enough to integrate the stiffness matrix (94), (96), (98) and (100) with satisfying accuracy.

9. Fictitious stiffness and MacNeal stabilization

In the field of shell kinematic, there is no rotation around the normal axis (\(\theta_n\)). Therefore, the stiffness matrix \([k]\) (101) will contain the value zero at the slots for nodal variables \(\theta_n\). As a result, it will arise four spurious modes in shell element stiffness matrix. If all elements are placed into a plane that results with all nodes coplanar, the stiffness matrix will have a spurious mode with respect to rotations around normal to the shell (so called drilling rotations [64]). Therefore, to avoid the difficulties dealing with spurious modes, we use a fictitious stiffness. With the addition of fictitious stiffness, three spurious modes will vanish, while the other spurious mode will be eliminated by MacNeal stabilization [52].

\[ \Pi_{int} = \Pi_{int}^0 + \Pi_{int}^b + \Pi_{int}^d \]  

(102)

We define a fictitious stiffness:

\[ \Pi_{int}^b = \frac{1}{2} H_{xx} 10^{-3} \int_{A} (\theta_{x} \theta_{x} + \theta_{y} \theta_{y} + \theta_{z} \theta_{z}) dA \]

\[ \Pi_{int}^d = \frac{1}{2} (\theta_{n}) [k_{n}] [\theta_{n}] \]  

(103)

\[ \theta_b(\xi,\eta) = \sum_{i=1}^{4} N(\xi,\eta) \theta_{i} \]

\[ \theta_d(\xi,\eta) = \sum_{i=1}^{4} N(\xi,\eta) n_{xi} n_{yi} n_{zi} > \theta_{i} \]

(104)

where:

\[ \langle \theta_b \rangle = [\theta_{b}]^T = [\theta_{x} \theta_{y} \theta_{z} \cdots] \]  

(105)

\[ \begin{bmatrix} \theta_{x} \\ \theta_{y} \\ \theta_{z} \end{bmatrix} = [C]^T \begin{bmatrix} \theta_{x} \\ \theta_{y} \\ \theta_{z} \end{bmatrix} \]  

(106)

Matrix \([k_{n}]\) is expanded into matrix \([k_{n}]_{12 \times 12}\) to adjust the nodal variables in the element stiffness matrix.

We define a fictitious stiffness according to Mac Neal stabilization, terms leading to:

\[ \Pi_{int}^d = \frac{1}{2} G_{LT} 10^{-3} \int_{A} (\theta_{n} \theta_{n}) dA = \frac{1}{2} (u_{n}) [k_{n}] [u_{n}] \]  

(107)

where we used a small arbitrary factor of stabilization of \(10^{-3}\) that will not affect the results but will enable to avoid singularities. The final form of the stiffness matrix is:

\[ [\tilde{k}] = [k] + [k_{n}] + [k_{n}^d] \]  

(108)

In this format, it is important to notice that matrix \([k_{n}]_{12 \times 12}\) is expanded into matrix \([k_{n}]_{18 \times 24}\) to adjust the nodal variables in the element stiffness matrix. Therefore, the rank of matrix \([k_{n}]\) is three and rank of matrix \([k_{n}]\) is one. The addition of small fictitious stiffness \([k_{n}]\) and \([k_{n}^d]\) will not affect the precision and the rate of convergence. Matrix \([k_{n}]\) eliminates the numerical singularity in the element when the four nodes are coplanar. Finally, the DKMQ24 element has rank = 18, with 6 rigid body modes without any spurious mode and without any spurious constraint when the four nodes are coplanar.

10. Numerical simulations

To validate our new DKMQ24 shell element for composite structures, we will use the tests proposed by Srinivas [65] and Pagano and Hatfield [66,67] for plate problems. Moreover, for composite shell problems we consider the test proposed by Varadan and Bhaskar [68], along with a new hyperbolic paraboloid shell test.

The convergence of finite element formulation generally is measured by using the displacements or stresses at one point of the structures as a function of mesh refinement. But it is better to consider, the method called s-norm, proposed in [69,70] will be used to get the behavior of the whole structure and to evaluate uniform and optimal convergence. The s-norm, defined in [69,70], is briefly presented in the Appendix A.

10.1. Simply supported (SS) under uniform loading of a sandwich plate

For the first test to validate our new element, we will use the test proposed by Srinivas [65]. Fig. 11 shows the details of this test in terms of chosen geometric and material properties. We will only analyze one quarter with area ABCD. The layer 2 (core) properties are proportional to those of the skin (\(C = 1\), \(C = 10\), and \(C = 50\) are evaluated in this test).

Table 2 reports the results of central deflection at point C for \(L/h = 10\), where the analytical computation result based on 3D elasticity theory [65] is used as the reference solution. The central displacement of point C is expressed in the form:

\[ \begin{align*}
V &= \frac{4}{3} E_{1} \left( \frac{h}{L} \right)^{3} \int_{0}^{L} \left( \frac{u}{L} \right) dL \\
W &= \frac{4}{3} E_{2} \left( \frac{h}{L} \right)^{3} \int_{0}^{L} \left( \frac{v}{L} \right) dL \\
T &= \frac{4}{3} G_{12} \left( \frac{h}{L} \right)^{3} \int_{0}^{L} \left( \frac{\tau}{L} \right) dL \\
\end{align*} \]

(109)

where \(E_{1}\) and \(E_{2}\) are the Young’s moduli in the axial direction of the skin and core, \(G_{12}\) is the shear modulus between the skin and core, and \(h\) is the thickness of the core. The boundary conditions are: \(u = 0\) along \(AB\) and \(W = 0\) along AD. Symmetrical conditions: \(\theta = 0\) along BC, \(V = 0\) along DC.

![Fig. 11. Simply supported square sandwich plate under uniform loading.](image-url)
We have also checked that DKMQ24 and MITC4 [27] give similar results. To get the behavior of the whole structure, the $s$-norm test is performed. Figs. 12 and 13 present the convergence behavior of DKMQ24 and MITC4 [27] elements in composite application using \( L/h = 4, 10, 100, 1000 \) and 10,000. The result of DKMQ24 with \( N \times N = 128 \times 128 \) is used as reference solution. We found that the result of DKMQ24 element are similar to MITC4 for thick plate problem. However, in thin plate problem, DKMQ24 element leads to smaller errors.

To study the sensitivity of the DKMQ24 element, we analyze the same test using distorted meshes presented in Fig. 14. The central deflection at point $C$ for $L/h = 10$ compared to the reference values of Srinivas [65] is presented in Table 3. The two elements give the results

\[
W_C = \frac{W_C \cdot G_{r(Core)}}{k_f}
\]

All numerical results obtained are very close to the reference solution. We have also checked that DKMQ24 and MITC4 [27] give similar results.

that converge to the reference solution for all value of $C$. Figs. 15 and 16 present the convergence behavior of DKMQ24 and MITC4 [27] elements by using the distorted mesh. We found that the behavior of DKMQ24 is similar to the MITC4 element for thick plate problem. Moreover, this test reveals that DKMQ24 and MITC4 elements in composite application are not very sensitive to mesh distortion.

10.2. Non-symmetric sandwich plate

We analyze simply supported square sandwich plate with non-symmetric layer arrangement under uniform loading $f_z$. For the plate section non-symmetry, there is a coupling between bending and membrane effects. We can see the data for this test in Fig. 17. Because of symmetry, in the loading and boundary conditions, we only analyze one quarter with
area ABCD. The layer 2 (core) properties are proportional to those of layers 1 and 3, where $E$ and $G$ values of the core are 10 times weaker than those of the skin. We check the convergence of numerical results computed by DKMQ24 against the reference solution by Srinivas [65].

We can validate our element DKMQ24 by comparing the vertical displacement in point $C$ against the reference solution by Srinivas [65] and also provide a comparison to the other element. The reference of central displacement is given by

$$W_C = \frac{W_{GZ}(\text{Core})}{h_f}$$

The central deflection at point $C$ for $L/h = 10$ compared to the

reference values of Srinivas [65] is presented in Table 4. All the numerical results obtained are very close to the reference solution. We have also checked that DKMQ24 and MITC4 [27] give similar results.

10.3. Simply supported 3-layered and 9-layered square plate under sinusoidal pressure load

In this test, we analyze a simply supported 3-layered and 9-layered unidirectional square laminated, composite plate with \( L = 1000 \) and different thickness, using DKMQ24 shell element. We carry out the analysis for uniform and distorted mesh, and compare the performance of DKMQ24 element against MITC4 [27] element. This test is proposed by Pagano and Hatfield [66,67], with the details presented in Fig. 18.

The solution for vertical displacement in point \( C \) is expressed with the following form:

\[
W_C = \frac{e^{\pi Q}}{128 \pi^4 L_e} \left[ \frac{L_e}{L} \cdot \frac{Q}{4G_{L,T}} \right] + \left( \frac{e^{\pi Q}}{128 \pi^4 L_e} \right) \left( \frac{L_e}{L} \cdot \frac{Q}{4G_{L,T}} \right) \left( 1 + 2 \pi^2 Q \right)
\]

We can see in Tables 5 and 6 the computed central displacement for 3-layered and 9-layered matches very well the reference solution given by Pagano and Hatfield [66,67] when using uniform mesh. We also found a good agreement between DKMQ24 and MITC4 [27] elements. Figs. 19 and 20 show the convergence behavior of DKMQ24 and MITC4 elements in composite application. When using \( L/h = 4, 10, 100, 1000 \) and results of DKMQ24 with \( N \times N = 128 \times 128 \) as the reference solution, we find again that DKMQ24 element has similar behavior with MITC4 element for thick plate problem. On the contrary, in thin plate problem, DKMQ24 element gives smaller error than MITC4 element.

Fig. 19. Convergence behavior of 3-layered square plate by using s-norm with uniform mesh.
The correlation between the numerical results computed both by DKMQ24 and MITC [27] elements with the reference solution. Figs. 21 and 22 show the convergence behavior of DKMQ24 and MITC4 [27] elements in composite plate application by using $s$-norm. For uniform mesh, $L/h = 4, 10, 100, 1000$ and $10,000$ and the results of DKMQ24 with $N \times N = 128 \times 128$ taken as reference solution, we found again that DKMQ24 element has similar behavior with MITC4 element in thick plate problem. Moreover, the two elements are not sensitive to the mesh distortion.

### 10.4 Three-layered Cylindrical Shell with Sinusoidal Pressure

In this test, we will analyze a three-layered cylindrical shell with sinusoidal pressure. Because of symmetry, we will analyze only one quarter of the shell, with the area $ABCD$ shown in Fig. 23. This test was first analyzed by Ren [71], providing an analytical solution, which was then revisited by Varadan et Bhaskar [68] who proposed a solution based on 3D elasticity.

We compare the vertical displacement at point $C$ with the reference solution in [68]. Table 9 shows the comparison of DKMQ24 and MITC4 elements with reference solution for different ratios of $R/h$. The reference value of central displacement is given by [68]:

$$W_C = \frac{10E}{15\pi^2 R^4} W_C ; S = \left( \frac{R}{R} \right)$$
By using NELT = 20, 80, 320, 1280 and 5120 (NELT = 20 shows in Fig. 23) and R/h = 50, 100 and 500, the vertical displacement of point C are presented in Fig. 24 and Table 9. The two elements give very good results compared to the reference solution. We can see that DKMQ24 element converges faster than MITC4 [27] element.

10.5. Ten-layered cylindrical shell with sinusoidal pressure

In this test, we will analyze ten-layered cylindrical shell loaded with sinusoidal pressure. Because of symmetry, we will analyze only the area ABCD in the Fig. 25. This test has been studied by Ren [71] analytical solution, then revisited by Varadan et Bhaskar [68] who proposed a reference solution based on 3D elasticity.

We compare the vertical displacement of point C with the reference solution in [68]. In Table 10, which shows the comparison of numerical results obtained with DKMQ24 and MITC4 [27] against the reference solution for different ratio of $R/h$. The reference value of central displacement is given by [68]:

$$W_c = \frac{10E_t}{f_c S^4 h} W_c; S = \left(\frac{R}{R}\right)$$

Similarly, to the previous test, we use NELT = 20, 80, 320, 1280 and 5120 (NELT = 20 shows in Fig. 25) and $R/h = 50, 100$ and 500. The computed numerical results for vertical displacement at point C are presented in Fig. 26 and Table 10. The two elements give very good results converging to the reference solution. We can see that DKMQ24 element converges faster than MITC4 element.

10.6. Hyperbolic paraboloid shells

Another problem is the problem of a hyperbolic paraboloid composite shell with a distributed load in the normal direction $f_c$. Fig. 27 presents the geometry and mechanical characteristic of this problem.

This particular shell has a negative Gaussian curvature with boundary conditions along the straight lines. The projection is a rectangular-shape, with bases $2a \times 2a$, and clamped on the sides. This
shell geometry corresponds to a shallow shell. The layer 2 (core) properties are proportional to those of layers 1 and 3, where $E$ and $G$ values of the core are $C$ times weaker than those of the skin ($C = 1, C = 10$, and $C = 50$ are evaluated in this test).

Table 11 and Fig. 28 present the convergence of the deflection $W_C$ ($L/h = 100$) of hyperbolic paraboloid shells.

**Fig. 28.** Convergence of central deflection $W_C/W_C$ (DKMQ24 with mesh $64 \times 64$) of hyperbolic paraboloid shells.

11. Conclusions

The new four nodes and 24 $dof$ quadrilateral shell element DKMQ24, using incomplete quadratic interpolation functions for the rotations, has been presented and evaluated for thick and thin shell composite problems. The presents DKMQ24 element is valid for any-shell principal curvatures and position on the four nodes on the middle surface due to proper coupling between membrane and bending displacement to define the bending strain [11,52]. DKMQ24 element can equally reproduce the behavior in accordance with the theory of Kirchhoff and Reissner-Mindlin, due to the use of a shear influence factor $\phi_k$ which is a function of shell thickness ratio.

This also explains the position of the DKMQ24 element relative to the MITC4 [27] and DKQ24 [62] shell elements. The DKMQ24 element will become identical to the MITC4 element when $\phi_k$ is very large. On the other hand, the DKMQ24 element become identical to the DKQ24 [62] element when $\phi_k$ is very small.

The results of the analysis show that this element can pass all standard convergence tests, without membrane locking. It is also free of shear locking, as the DKMQ plate element [41]. In bending dominated problems, results obtained with DKMQ24 element are very good and the convergence is faster than with MITC4. This is due to the quadratic interpolation functions for the rotations used in DKMQ24.

Appendix A

A.1. S-NORM METHOD

Uniform and optimal convergence of elements can be assessed using $s$-norm tests as defined in [72,73,70,74].

The relative error is computed using the general expression:

$$E_s = \frac{||\Pi_{\text{Ref}}^{\text{s}}||^2}{||\Pi_{\text{int}}^{\text{s}}||^2} = \frac{||\Pi_{\text{Ref}}^{\text{def}} - \Pi_{\text{Ref}}^{\text{int}}||^2}{||\Pi_{\text{Ref}}^{\text{def}}||^2}$$

(A-1)

where $||\Pi_{\text{Ref}}^{\text{def}}||^2$ refers to the strain energy of the reference solution which can be defined by an analytical expression or numerically by using a very fine mesh with “good” elements.

Even if an analytical solution is available it is not always easy to express $||\Pi_{\text{Ref}}^{\text{def}}||^2$ and usually a very fine mesh is used. For the present plate bending problems, we then have:

$$||\Pi_{\text{Ref}}^{\text{def}}||^2 = \sum_{i=1}^{\text{NELT}} ||\Pi_{\text{Ref}}^{\text{def}}||_{i}^2$$

(A-2)

NELT is the total number of elements in the reference mesh.
\[
\begin{align*}
|\Pi_{\text{int}}^{\text{RF}}|^2 &= \frac{1}{2} \int_\Omega \langle N_{\text{ref}} \rangle [H_{\text{ref}}^{-1}]^{-1} \langle N_{\text{ref}} \rangle \text{d}A + \\
&\frac{1}{2} \int_\Omega \langle M_{\text{ref}} \rangle [H_{\text{ref}}^{-1}]^{-1} \langle M_{\text{ref}} \rangle \text{d}A + \\
&\frac{1}{2} \int_\Omega \langle N_{\text{ref}} \rangle [H_{\text{ref}}^{-1}]^{-1} \langle N_{\text{ref}} \rangle \text{d}A + \\
&\frac{1}{2} \int_\Omega \langle M_{\text{ref}} \rangle [H_{\text{ref}}^{-1}]^{-1} \langle M_{\text{ref}} \rangle \text{d}A + \\
&\frac{1}{2} \int_\Omega \langle T_{\text{ref}} \rangle [H_{\text{ref}}^{-1}]^{-1} \langle T_{\text{ref}} \rangle \text{d}A
\end{align*}
\tag{A-3}
\]

and

\[
|\Pi_{\text{int}}^{\text{RF}} - \Pi_{\text{int}}^{\text{FE}}|^2 = \sum_{i=1}^{\text{NELT}} |\Pi_{\text{int}}^{\text{RF}} - \Pi_{\text{int}}^{\text{FE}}|^2
\tag{A-4}
\]

\[
|\Pi_{\text{int}}^{\text{RF}} - \Pi_{\text{int}}^{\text{FE}}|^2 = \frac{1}{2} \int_\Omega \langle \Delta N \rangle [H_{\text{ref}}^{-1}]^{-1} \langle \Delta N \rangle \text{d}A + \\
\frac{1}{2} \int_\Omega \langle \Delta M \rangle [H_{\text{ref}}^{-1}]^{-1} \langle \Delta M \rangle \text{d}A + \\
\frac{1}{2} \int_\Omega \langle \Delta N \rangle [H_{\text{ref}}^{-1}]^{-1} \langle \Delta M \rangle \text{d}A + \\
\frac{1}{2} \int_\Omega \langle \Delta M \rangle [H_{\text{ref}}^{-1}]^{-1} \langle \Delta N \rangle \text{d}A + \\
\frac{1}{2} \int_\Omega \langle \Delta T \rangle [H_{\text{ref}}^{-1}]^{-1} \langle \Delta T \rangle \text{d}A
\tag{A-5}
\]

where

\[
\langle \Delta N \rangle = \langle (N_{\text{ref}}) - (N) \rangle \quad \langle \Delta M \rangle = \langle (M_{\text{ref}}) - (M) \rangle \quad \langle \Delta T \rangle = \langle (T_{\text{ref}}) - (T) \rangle
\tag{A-6}
\]

We integrate over the element area using Gauss point (2 × 2) in the reference mesh. From the result of each element of the target mesh, we have

\[
\left\langle \Pi_{\text{int}}^{\text{RF}} - \Pi_{\text{int}}^{\text{FE}} \right\rangle = \left\langle \Pi_{\text{int}}^{\text{RF}} \right\rangle - \left\langle \Pi_{\text{int}}^{\text{FE}} \right\rangle
\tag{A-7}
\]

where \(c\) is a constant and \(p\) is the interpolation order. We use reference lines for Eq. (A-7) with \(p = 1\) corresponding to a linear convergence.
